Purpose: To analyze risk factors for extramacular drusen (EMD) in patients with age-related macular degeneration (AMD) and healthy control individuals.
Methods: This case-control study included 1,520 patients from the prospective multicenter European Genetic Database (EUGENDA). Color fundus photographs and optical coherence tomography scans were evaluated for the presence of AMD and EMD. EMD was considered present if ten or fewer drusen including at least one intermediate-sized drusen were detected outside the macula. Association of EMD was evaluated with various genetic and non-genetic risk factors (31 single nucleotide polymorphisms, systemic complement activation, smoking, cardiovascular factors, and sunlight exposure) using logistic regression models adjusted for age, gender, and AMD.
Results: EMD was found in 608 subjects (40%) and AMD in 763 (50%) of 1,520 participants. EMD was strongly associated with AMD ($p = 2.83 \times 10{-}63$, odds ratio [OR] 7.63). After adjustment for AMD, age ($p = 0.06$, OR 1.02), female gender ($p = 3.34 \times 10{-}24$, OR 4.44), history of sunlight exposure ≥ 8 h /day ($p = 0.0004$, OR 1.99), serum complement activation ($p = 0.004$, OR 1.61), and polymorphisms in ARMS2 ($p = 0.00016$, OR 1.43) and CFI ($p = 0.043$, OR 1.20) were identified as risk factors for EMD. The final prediction model including these variants showed an area under the curve of 0.820.
Conclusions: The comprehensive analysis of various risk factors revealed a common genetic and pathological pathway of EMD with AMD. Future longitudinal studies are needed to evaluate the role of EMD in otherwise healthy subjects as an expanded phenotype of AMD.

Age-related macular degeneration (AMD) is a multifactorial progressive disease that is one of the leading causes of visual impairment in the industrialized world. The disease is recognized by the presence of drusen and RPE abnormalities in the macula [1]. However, neither the formation of drusen nor RPE abnormalities are restricted to the macula [2-6]. Although histopathological findings and numerous clinical studies have pointed out the high prevalence of extramacular or peripheral changes in patients with AMD [2-9], the most accepted AMD classifications and grading schemes are limited to the posterior pole [10-12].

Multiple genetic variants involved in the complement system, extracellular matrix, and lipid metabolism contribute to AMD pathogenesis and drusen formation in the macula [13]. Additionally, non-genetic risk factors, such as aging, obesity, smoking, and increased sunlight exposure during young ages, are thought to be involved [14]. Despite increasing knowledge about risk factors for drusen formation within the macula, little is known regarding extramacular drusen (EMD). Contradictory associations of EMD with major AMD-associated polymorphisms in the complement Factor H *(CFH)* gene (Gene ID: 3075, OMIM 134370) and smoking have been reported [2-4,6].

This study aimed to investigate several genetic and non-genetic risk factors for the presence of EMD in patients with and without AMD. Furthermore, we aimed to create a multivariate prediction algorithm for the presence of EMD.

METHODS

This case-control study evaluated 2,278 individuals from EUGENDA (multicenter European Genetic Database). The EUGENDA database was designed to prospectively collect questionnaires, imaging data, and blood samples to evaluate genetic and non-genetic risk factors in patients with AMD

Correspondence to: Sandra Liakopoulos, Department of Ophthalmology, University Hospital of Cologne, Kerpener Str. 62, 50924 Cologne, Germany; Phone: 0221 478 7772; FAX: 0221 478 97808; email: sandra.liakopoulos@uk-koeln.de

and healthy control persons older than 55 years of age. The study was performed according to the Declaration of Helsinki and the Medical research Involving Human subjects Act (WMO), adhered to the ARVO statement on human subjects and was approved by the ethics committee of the University hospitals of Cologne (Germany) and Nijmegen (Netherlands). Before enrollment in EUGENDA, written informed consent was obtained from all participants.

Questionnaires: Medical data obtained from interviewer-assisted questionnaires included age, gender, body mass index (BMI; categorized as < 18.5, 18.5–25.0, ≥ 25.0), history of cardiovascular risk factors (CVS; myocardial infraction, stroke and history of transient ischemic attack, categorized as yes/no), hypertension (yes/no), diabetes (yes/no), allergy (yes/no), history of smoking (categorized as never/ever), and history of past sunlight exposure (categorized as < 4 h/day, 4–8 h/day, ≥ 8 h/day).

Retinal imaging and grading: Grading of images was performed by certified reading center graders (LA, TS, AB), as previously described. The presence of AMD and EMD was evaluated using color fundus photography (Cologne: Canon UVI fundus camera using a 40° field of view; Canon, Tokyo, Japan, and Nijmegen: Topcon TRC 50IX fundus camera using a 50° field of view; Topcon). Spectral domain optical coherence tomography (SD-OCT, Spectralis HRA system; Heidelberg Engineering, Heidelberg, Germany) was additionally used to differentiate between drusen and RPE abnormalities, and to identify signs of choroidal neovascularization (CNV) and geographic atrophy. If available, fluorescein angiography (FA) images were also evaluated.

In this study, EMD was considered present if at least ten drusen were detected on the field of two images outside the 6 mm Early Treatment Diabetic Retinopathy Study (ETDRS) grid, including at least one intermediate-sized drusen (63–124 µm; Figure 1). Cases with one to nine drusen or with only drusen less than 63 µm regardless of the number were defined as threshold cases and were excluded from analysis.

AMD was defined as the presence of either small macular drusen (< 63 µm) in combination with pigmentary changes, intermediate-sized drusen (63–124 µm), or large drusen (≥ 125 µm) within 6 mm of the ETDRS grid centered on the fovea. Late forms of AMD included the presence of CNV and any geographic atrophy or either.

Serum measurements and genotyping: Peripheral blood samples for genetic analyses and complement measurements were obtained by standard protocol. Serum samples were centrifuged after coagulation by room temperature and were stored at -80 °C within 1 h of collection. Complement activation levels (ratio between activation fragment C3d and complement component C3 (C3d/C3 ratio)) were measured in serum as previously described [15]. Genotyping was performed for 41 single nucleotide polymorphisms (SNPs) in AMD-associated genes using the KASPar SNP Genotyping System (LGC Genomics, Berlin, Germany; Appendix 1). Only SNPs with minor allele frequency ≥ 0.1 were tested in this analysis (n = 31).

Statistical analysis: All AMD-associated variables were assessed to determine their association with presence of EMD using logistic regression models adjusted for age, gender and AMD (yes/no), unless otherwise mentioned. Thereafter, variables with a p value of less than 0.10 were selected for inclusion in the multivariable logistic regression model. The discriminative accuracy of this model was evaluated using receiver operating characteristic (ROC) curves and calculation of their corresponding area under the curve (AUC) for different subgroups. Statistical analysis was performed using IBM SPSS Statistics software, version 22.0 (IBM Corporation, Armonk, NY).

RESULTS

Of 2,278 individuals available in the EUGENDA cohort, a total of 445 cases were excluded from analysis due to insufficient quality of the retinal images, absent retinal images of both eyes, or the presence of confounding retinal disease (e.g., diabetic maculopathy, high myopia [≥ –6 diopters], or retinal detachment). Of the remaining 1,833 cases, EMD was considered present in 608 subjects (33%), whereas no EMD was seen in 912 subjects (50%). A total of 313 cases (17%) were assessed as "threshold" cases (one to nine drusen outside the ETDRS grid or only small drusen) and were excluded from further analysis, leaving 1,520 cases in the final analysis cohort. In this cohort, AMD was present in 763 patients (50%). The baseline characteristics of all cases are shown in Table 1.

Risk factors for the presence of EMD:

AMD phenotype—The presence of EMD was strongly associated with AMD ($p = 2.83 \times 10^{-63}$, odds ratio [OR] 7.63, 95% confidence interval (CI): 6.06–9.66). EMD risk was higher in eyes with late AMD ($p = 1.70 \times 10^{-51}$, OR 11.25, 95% CI:8.17–15.31) compared to eyes with early or intermediate AMD ($p = 4.89 \times 10^{-30}$, OR 5.70, 95% CI:4.23–7.69).

Genetic risk factors—Among the 31 tested SNPs, only *ARMS2* rs10490924 (Gene ID: 387715, OMIM 611313) and *CFI* rs10033900 (Gene ID: 3426, OMIM 217030) were associated with the presence of EMD in the logistic regression

Figure 1. Example of the extramacular drusen phenotype.

analyses adjusted for age, gender, and AMD (yes/no): *ARMS2* rs10490924 (p = 0.00016, OR 1.43 and *CFI* rs10033900 (p = 0.043, OR 1.20). In contrast, the *CFH* rs1061170 risk allele showed no statistically significant association with the presence of EMD (p = 0.40, OR 1.08; Appendix 1). Associations of tested SNPs with AMD are provided in Appendix 2.

Non-genetic risk factors—After adjustment for AMD, the presence of EMD was associated with age (p = 0.06, OR 1.02, 95% CI:1.00–1.03) and female gender ($p = 3.34 \times 10^{-24}$, OR 4.44, 95% CI:3.33–5.91). Of all patients with EMD, 74.7% were female, whereas gender distribution among AMD patients was 61.3% female versus 38.6% male (female gender in AMD: p = 0.065 OR 1.23).

Furthermore, EMD was associated with the systemic complement activation C3d/C3 ratio (p = 0.004, OR 1.61, 95% CI:1.16–2.25) and with a history of sunlight exposure ≥ 8 h (p

Table 1. Baseline characteristics of all subjects.

AMD: Age-related macular degeneration, BMI: Body mass Index, EMD: Extramacular drusen, HDL: High density lipoprotein, *Chi-square Test, † Mann–Whitney-U Test, In: natural logarithm of.

= 0.0004, OR 1.99, 95% CI:1.35–2.92). History of smoking, hypertension, cardiovascular disease, diabetes, allergy, and increased BMI were not associated with EMD.

Multivariate analysis—We performed a multivariate final prediction model for the presence of EMD including all significantly associated parameters: age, gender, SNPs in the *ARMS2* and *CFI* genes, AMD severity (early/intermediate or late AMD), C3d/ C3 ratio, and history of sunlight exposure ≥ 8 h (Table 2). Analysis of the ROC curve of this risk prediction model for EMD revealed an AUC of 0.820.

Subgroup analysis of cases with no AMD: Of 757 subjects without AMD, EMD was detected in 18% of cases (n = 134). The mean age of this subgroup was 71.06 ± 5.830 years, which was statistically significantly different in comparison to patients with AMD and EMD (mean age 75.58 ± 8.450 years, p<0.001). Systemic complement activation levels were not statistically significantly different between the two groups (p = 0.29).

Applying the multivariate final prediction model on the subgroup of cases with no AMD to avoid bias caused

by AMD severity (Table 3), we calculated a similarly strong predictive value with an AUC of 0.737.

DISCUSSION

Although an association of extramacular or peripheral retinal changes with AMD has been described in several previous reports [2-9], extramacular and peripheral changes may also be present in around 10%–31% of eyes with an otherwise completely healthy macula [7,16,17]. It is still unclear whether these extramacular or peripheral changes represent risk factors for development of AMD. After comprehensive analysis of genetic and non-genetic risk factors, we could show that age, female gender, history of sunlight exposure ≥ 8 h daily, serum complement activation, and polymorphisms in *ARMS2* and *CFI* are most predictive for the presence of EMD even if adjusted for the presence of AMD. These findings support the hypothesis of a common genetic and pathological pathway of EMD and AMD.

A role of local inflammation in macular drusen biogenesis due to dysregulation of the complement cascade was discussed in the early 2000s, as increased level of complement expression was found in human maculas [18]. Supporting the prominent role of dysregulated complement activation in the formation of EMD, we also found an association of EMD with increased systemic complement activation, and variants in the *CFI* gene. These findings suggest a possible pathological overlap between AMD and EMD formation with respect to complement system dysregulation. In this study, we found no association of EMD with the key AMD polymorphism *CFH* Y402H rs1061170, in concordance with previous reports [6,19]. This may be due to the smaller effect of this polymorphism on this specific EMD phenotype. Previous studies demonstrated an association between *CFH* Y402H and EMD; however, in those studies no stratification for the AMD phenotype was performed [2,4]. In contrast to other studies reporting an association of peripheral RPE changes with CFH polymorphisms [4,19], in this study we did not evaluate peripheral changes except EMD. Thus, the role of *CFH* Y402H for the development of peripheral age-related changes remains to be evaluated carefully in larger cohorts.

In this study, we detected a significant association between EMD and polymorphisms in the *ARMS2* and *HTRA1* (Gene ID: 5654, OMIM: 602194) genes, after adjustment for age, gender, and AMD. The association of EMD with *ARMS2* and *HTRA1* is a novel finding, which we did not detect in a previous study that included only 213 EMD cases, and thus, had limited power. Both genes are highly associated with AMD, and are involved in extracellular matrix (ECM) and Bruch's membrane (BrM) homeostasis [20-22], regulation of angiogenesis [23,24], and microglial cell activity [25,26]. An altered composition of BrM due to genetic predisposition may facilitate accumulation of macular and extramacular drusen [27] and may lead to an anti-inflammatory response involving complement cascade activation [26,28-31].

In this study, female gender was statistically significantly associated with EMD, but not with AMD. One possible explanation for an association of age-related findings with female gender is selection bias due to longevity. In the present cohort, however, the patients with EMD were significantly younger than the patients with AMD; thus, this does not seem to be a plausible explanation. Whether gender is a modifying factor for the presence of macular drusen is controversially discussed in the literature [32-34]. However, in line with results from this study, a recent genome-wide study that included more than 30,000 cases and controls revealed no association between gender and development of late AMD [35]. The reason for the strong association between female gender and EMD remains to be evaluated in further studies.

Although numerous studies have linked photo-oxidative stress to AMD pathogenesis and investigated the role of sunlight exposure as a risk factor for AMD, the results are inconsistent [36-44]. In this study, we identified sunlight exposure during previous working life (≥ 8 h daily) as an important risk factor for the development of EMD. Although

the exact pathogenic mechanism is not yet fully understood, identification of EMD at younger ages may prove to be a warning sign, which may trigger appropriate patient education and risk factor modification. Further longitudinal studies will be required, however, to confirm that EMD alone poses a risk for the development of subsequent AMD.

The frequency of EMD reported in the literature shows great variability due to discrepancies between cohorts regarding AMD severity, imaging modalities and protocols, and definitions of AMD and EMD. Various non-population-based studies evaluating drusen located outside the central 30° report a frequency of "peripheral drusen" of between 7% and 60% [2,4,5]. Lengyel et al. reported in their population-based study a frequency of 68% for peripheral drusen, with 57% of those patients classified as AMD [16]. The present result is in agreement with those results, revealing EMD in 62% of patients with AMD. However, Age-Related Eye Disease Study 2 (AREDS 2) reported peripheral drusen in almost every patient with AMD (98%) [7]. Histopathological studies demonstrated peripheral drusen in 88% of cases with macular degenerative abnormalities [3]. In line with these studies, and in agreement with our previous report [6], we can conclude that the presence of EMD is strongly associated with AMD. Nevertheless, even subjects with no signs of AMD may develop EMD: in AREDS 2, peripheral drusen were detected in 24% of cases without AMD [7], Lengyel et al. reported 10% peripheral changes in otherwise healthy subjects [16], and Nivison-Smith reported peripheral retinal findings in 31% of healthy subjects [17]. In this study, we report EMD in 18% of eyes without macular drusen and pigmentary changes. To understand the clinical relevance of those findings, longitudinal studies are needed to evaluate whether patients without current macular pathology may develop AMD in the future.

In an important limitation of this study, no ultrawidefield imaging was used. Furthermore, this study was a case-control study without longitudinal data, and thus, it remains unclear whether subjects without macular abnormalities in this study develop AMD in over time. Longitudinal observational studies are required to evaluate the long-term outcome in patients with EMD but without macular abnormalities. Only long-time observation may reveal whether EMD should be considered an expanded phenotype of AMD or not.

In this study, the analysis of genetic and environmental risk factors was restricted to those known to be risk factors for AMD; thus, there may remain unknown risk factors for EMD development. We attempted to minimize confounding factors by using a multivariate approach. Additionally, the sample size was limited, and larger studies may reveal further genetic associations, which were not statistically significant in this study.

In this study, we considered EMD to be present only if at least ten drusen were detected outside the ETDRS grid, including at least one intermediate-sized druse, in contrast to other studies that did not require specific minimum criteria regarding the size or number of drusen. With this approach, we aimed to exclude patients with only extramacular drupelets (small drusen < 63 µm diameter) or basal laminar drusen. Yet, the removal of threshold cases (1-9 drusen outside the ETDRS grid or only small drusen) might have caused also selection bias, since a large proportion of individuals were excluded from the analysis. Nevertheless, to the best of our knowledge, this is the first comprehensive study to analyze the combined effect of various genetic and non-genetic AMD risk factors on the presence of EMD.

In conclusion, we report a novel prediction model for the presence of EMD including various genetic and non-genetic risk factors. Predictive factors in this model include female gender, history of sunlight exposure ≥ 8 h/day, serum complement activation, and polymorphisms in *ARMS2* and *CFI*; thus, suggesting involvement of BrM, RPE abnormalities, and inflammatory processes in the pathogenesis of EMD. As AMD is a multifactorial disease, phenotypical changes such as EMD may present earlier in life and precede macular drusen. Therefore, longitudinal studies including subjects with EMD without macular abnormalities are needed to answer this question. If confirmed, the detection of the EMD phenotype may be a prompt for the physician to counsel the patient regarding modifiable risk factors and the need for close follow-up.
